

Ay1 – Lecture 13

Galaxies and Their Properties

Stephan's Quintet (HST)

13.1 Galaxy Morphology and the Hubble Sequence

Hickson 44 galaxy group (R. Kier)

The image displays a rich field of galaxies, characteristic of a galaxy group. In the center, there is a prominent edge-on spiral galaxy with a bright yellowish core. To its right, a face-on elliptical galaxy is visible. Above the central galaxy, there is a faint, irregular, and possibly interacting galaxy system. The background is filled with numerous individual stars of various colors, including white, yellow, and blue, scattered across the dark cosmic space.

Galaxies

- The basic constituents of the universe at large scales, and the building blocks of the large-scale structure
- Have *a broad range of physical properties*, which presumably reflects their evolutionary and formative histories, and gives rise to various morphological classification schemes (e.g., the Hubble type)
- Understanding of galaxy formation and evolution is one of the main goals of modern cosmology
- There are $\sim 10^{11}$ galaxies within the observable universe
- Typical total masses $\sim 10^8 - 10^{12} M_{\odot}$
- Typically contain $\sim 10^7 - 10^{11}$ stars

Morphological Classification and Galaxy Types

- The first step in any empirical science: look for patterns and trends, then try to understand the underlying physics
- Hubble proposed a scheme for classifying galaxies (the “tuning fork” diagram) in his 1936 book, *The Realm of the Nebulae*
- Subsequent refinements proposed by others - but not any fundamental change
- Nowadays we seek to define galaxy families through their physical properties and fundamental correlations - which reflect their physics and formative histories
- And look at the properties of *subsystems* within galaxies (e.g., disks, spheroids, halos, etc.), and deduce their origins and evolution

Hubble's Classification Scheme

Ellipticals classified by the apparent ellipticity

Spirals classified by the prominence of the spiral arms, and the presence of bars

Hubble thought (incorrectly) this was an evolutionary sequence, so ellipticals are called “early-type” and spirals “late-type” galaxies

Elliptical Galaxies

M87 in Virgo

Elliptical Galaxies

- Smooth and almost featureless:
no spiral arms or dust lanes
- Generally lacking in cool gas,
little or no current star formation
- Contain hot, X-ray gas
- Old, metal-rich stellar population
- Classified by the apparent
ellipticity:

$$\varepsilon = 1 - \frac{b}{a}$$

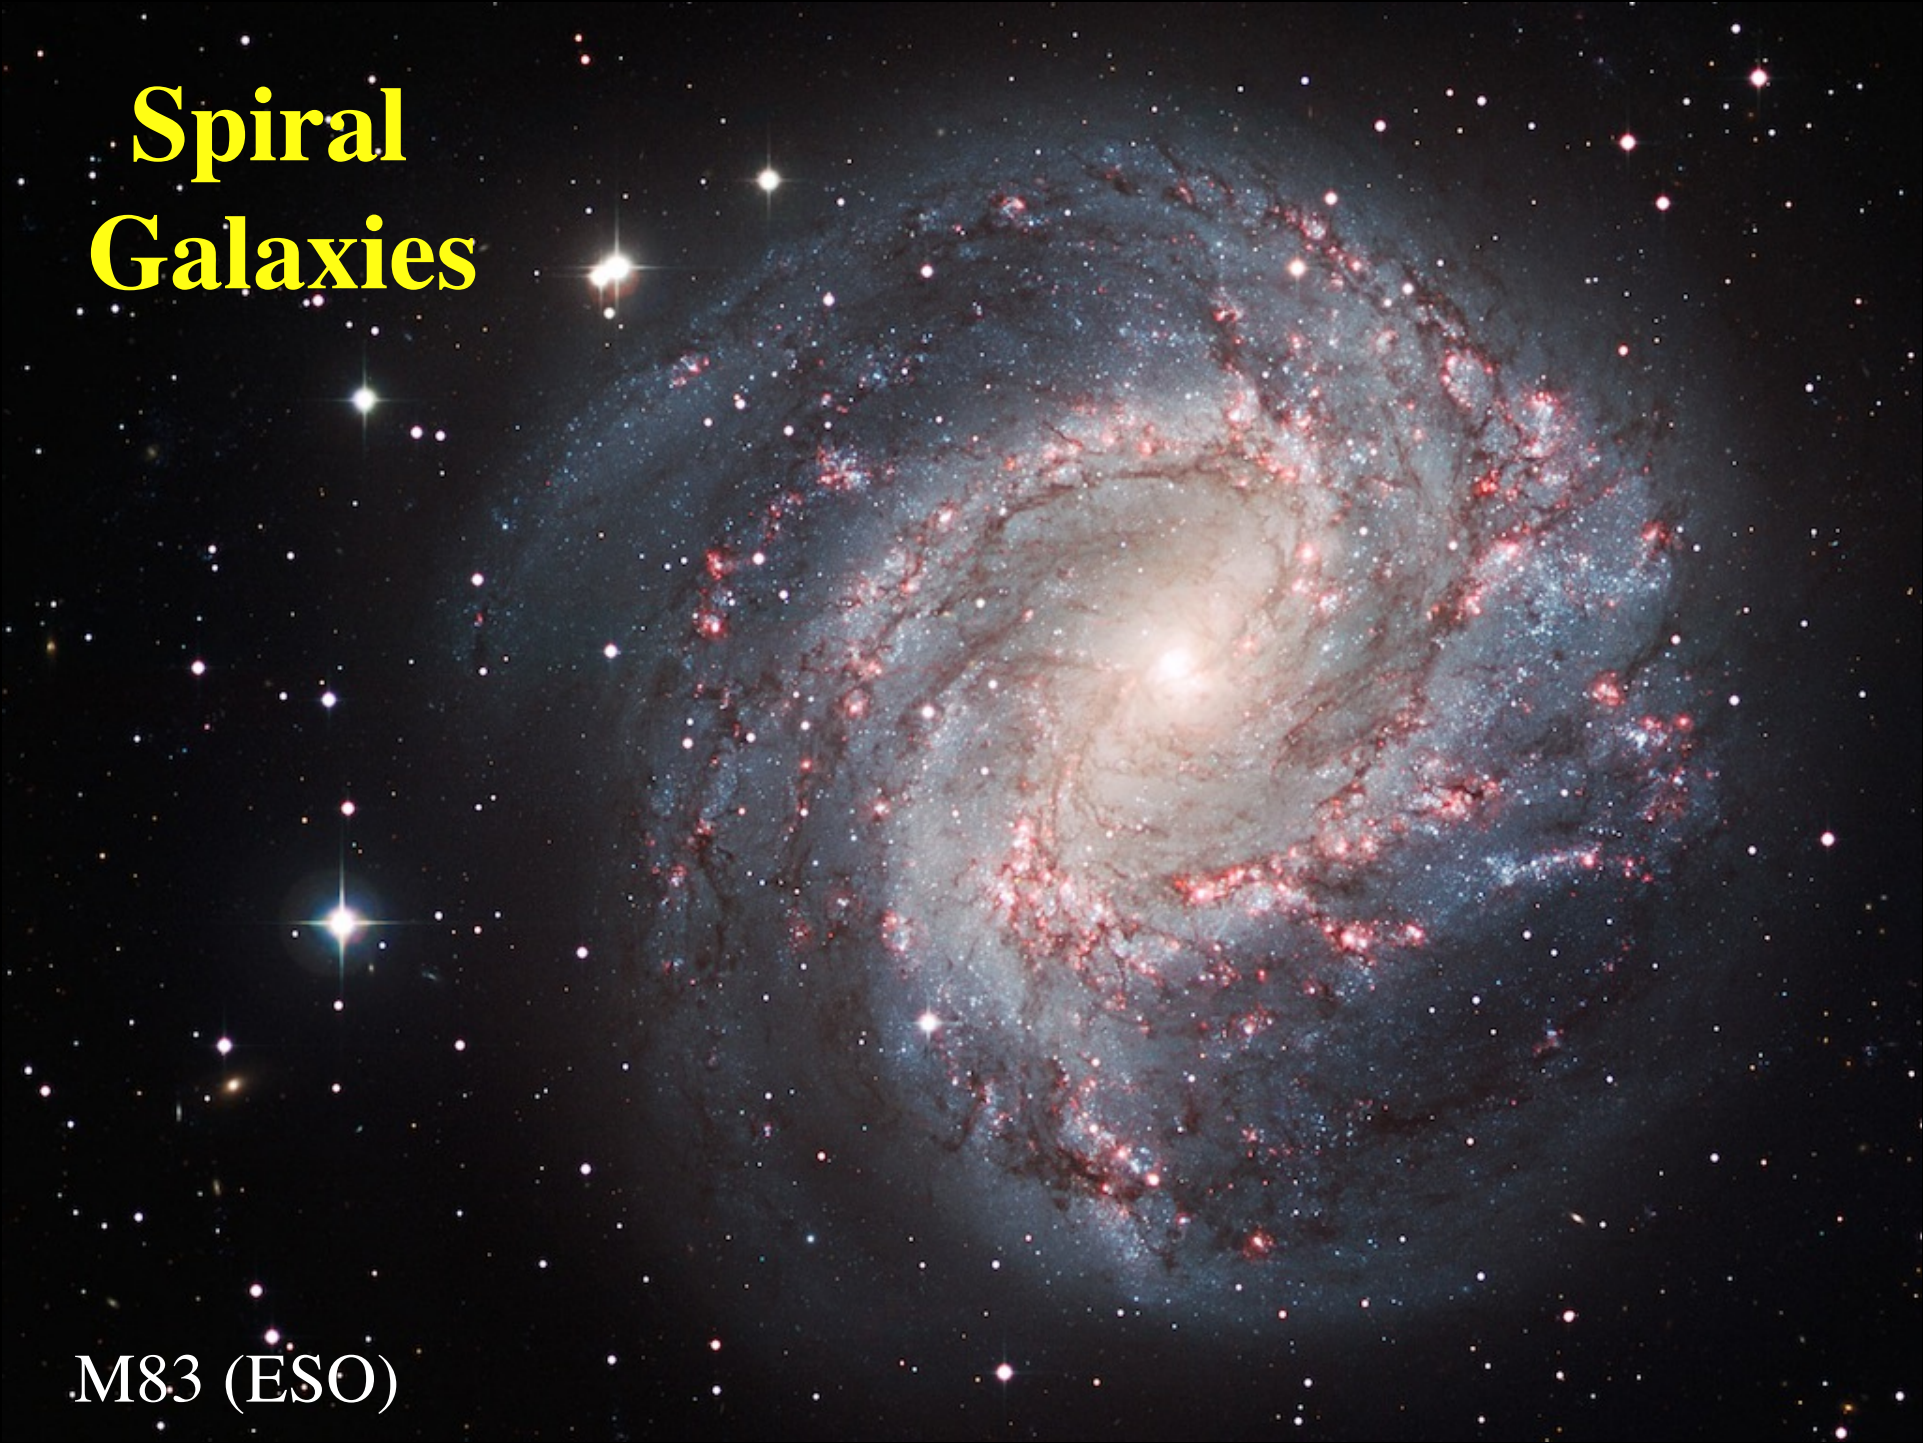

(not physically meaningful)

- Mostly found in clusters (denser
environments)

Spiral Galaxies

M83 (ESO)

A detailed image of the spiral galaxy M83 (ESO), also known as the Bode Galaxy. The galaxy is shown in a three-quarter view, revealing its central core and several prominent spiral arms. The arms are densely packed with stars, appearing as a mix of white and blue points of light. Interspersed among the stars are dark, reddish-brown filaments of interstellar dust. The central core is a bright, yellowish-white region. The galaxy is set against a dark, star-filled background, with several bright, out-of-focus stars visible in the foreground.

Spiral Galaxies

Named for their bright spiral arms, which are prominent due either to bright O and B stars (evidence for recent star formation), or to dust lanes.

Define two parallel sequences of spiral galaxies:

Sa

Sb

Sc

Sd

Central bulge becomes less important

Disk becomes more important

Spiral arms become more open and ragged

SBa

SBb

SBc

SBd

As above, except that these galaxies also have a central, linear **bar**, while the Sa, Sb... are unbarred

HST

**NGC 1300,
Barred Spiral Galaxy**

Barred Galaxies

- Half of all disk galaxies - Milky Way included - show a central bar which contains up to 1/3 of the total light
- Bars are a form of dynamical instability in differentially rotating stellar disks
- Presence of a dark halo stabilizes the disks against the bar formation, so disks are marginally unstable
- Bars are not density waves; they rotate with a pattern speed, and stars in the bar stay in the bar
- They can funnel gas to the center of the galaxy

NGC 6217 (HST)

Lenticular (S0) Galaxies

- Transition class between ellipticals and spirals are the S0 galaxies, also called **lenticulars**
- S0 galaxies have a rotating disk in addition to a central elliptical bulge, but the disk lacks spiral arms and active star formation
- They may have lost their gas through evolutionary processes
- They can also have a central bar, in which case they are labeled SB0

Sombrero galaxy

**Large Magellanic Cloud
Dwarf Irregular**

**Sagittarius Dwarf
Spheroidal →**

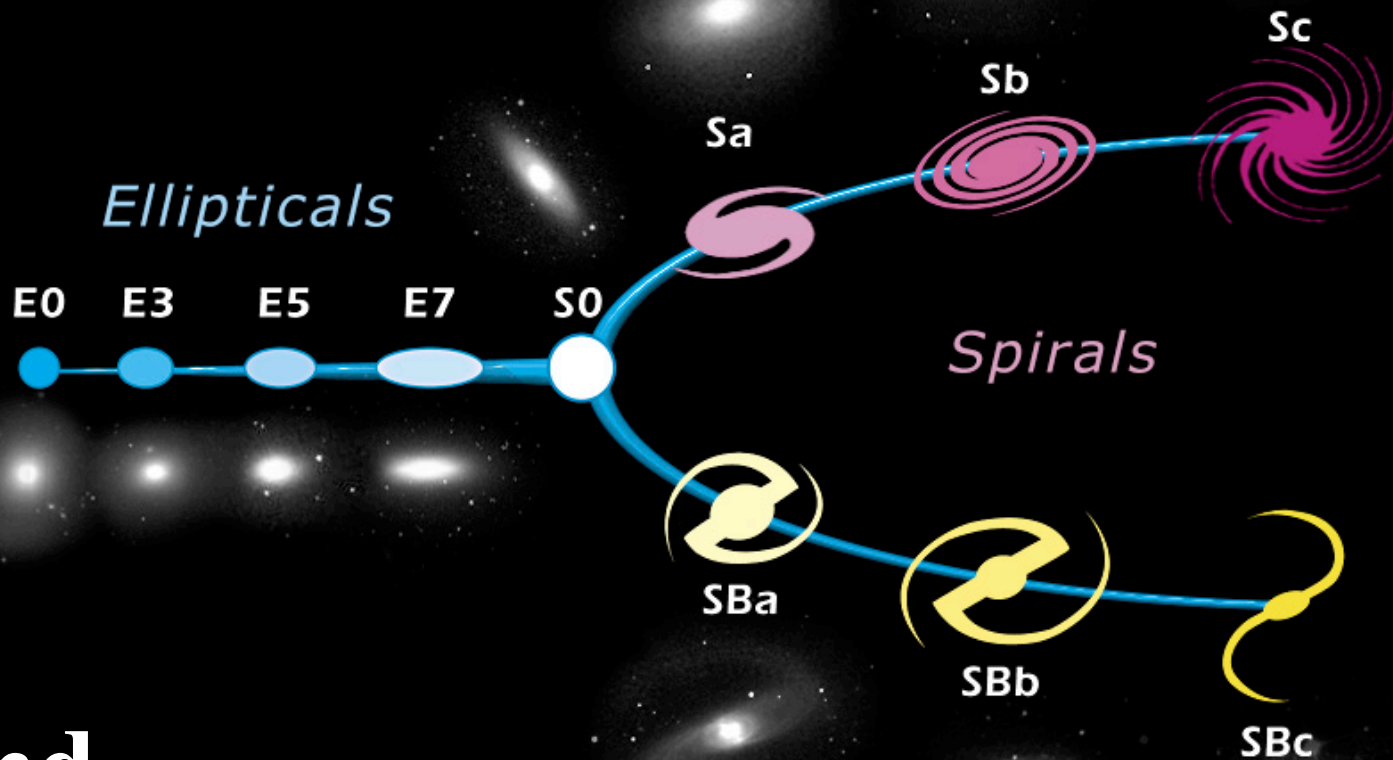

**← NGC 205 Dwarf
Elliptical**

Dwarf Galaxies

- Low-luminosity: $10^6 - 10^{10} L_{\odot}$, low-mass: $10^7 - 10^{10} M_{\odot}$, small in size, \sim few kpc
- Often low surface brightness, so they are hard to find!
- More than one family of objects:
 - Gas-poor, passive (dE and dSph)
 - Gas-rich, star forming
- Why are dwarf galaxies important?
 - Majority of galaxies are dwarfs!
 - Dwarf galaxies may be remnants of galaxy formation process: relatively simple systems, not merger products
 - Dwarf galaxies are currently being cannibalized by larger galaxies

13.2 Trends Along the Hubble Sequence...

... and
Their Origins

Traditional Galaxy Classification Is ...

Subjective - *especially for spiral galaxies*

Superficial - *based on appearance, not physical properties*
... and depending on the wavelength

Incomplete - *misses the major dichotomy of dwarfs and giants*
(not separated in the traditional Hubble sequence)

e.g., the nearby galaxy M81:

X-ray

UV

Visible

Near-IR

Far-IR

Galaxies look “clumpier” in the UV, and increasingly smoother at visible and longer wavelengths, due to young, luminous stars

The Meaning of Galaxy Classification

- **Galaxy morphologies and other properties reflect different formative and evolutionary histories**
- Much can be explained by considering galaxies as composites made of *two dominant visible components*:
 1. Old, pressure supported bulges, where most of the star formation occurred early on
 2. Young(er), rotationally supported disks, where star formation happened gradually and is still going on
- Note that we do not involve in this the dominant mass component - the dark matter
- Nevertheless, there are some important and meaningful trends along the Hubble sequence

Galaxy Properties and the Hubble Sequence

Hubble sequence turned out to be surprisingly robust: many, but not all, physical properties of galaxies correlate with the classification morphology:

Pressure support → Rotational support

Passive → Actively star forming

Red colors → Blue colors

Hot gas → Cold gas and dust

Old → Still forming

High luminosity density → Low lum. dens.

... etc.

But, for example, masses, luminosities, sizes, etc., do not correlate well with the Hubble type: at every type there is a large spread in these fundamental properties.

Interpreting the Trends Along the Hubble Sequence

- Probably the best interpretation of many of these is *a trend in star formation histories*:
 - Ellipticals and early type spirals formed most of their stars early on (used up their gas, have older/redder stars)
 - Late type spirals have substantial on-going star-formation, didn't form as many stars early-on (and thus lots of gas left)
 - Spirals are forming stars at a few M_{\odot} per year, and we know that there is \sim a few $\times 10^9 M_{\odot}$ of HI mass in a typical spiral
 - ✧ How long can spirals keep forming stars? It seems that some gas infall/resupply is needed
- These photometric/morphological properties also correlate with the dynamical properties

Star Formation History in Galaxies

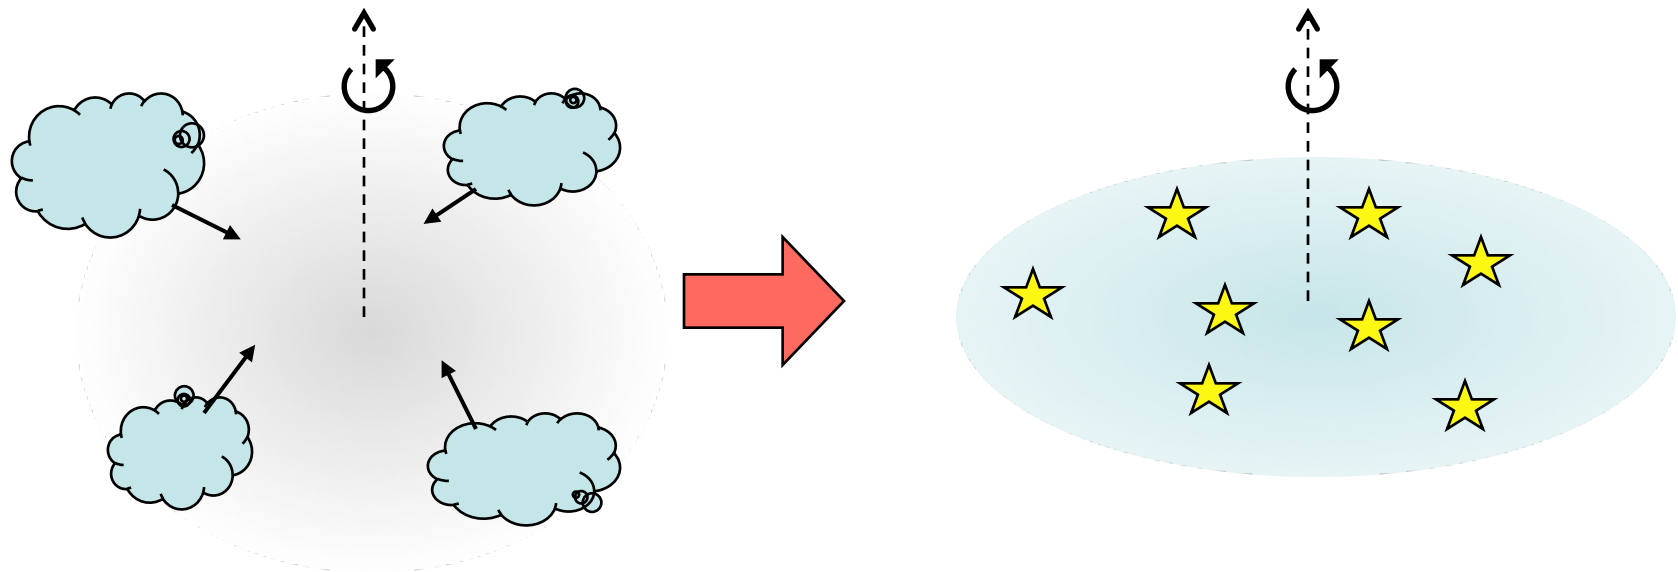

Formation of Galaxy Spheroids and Dynamics of Stellar Populations

Stars “remember” the dynamics of their orbits at the time of formation, since dynamics of stellar systems is dissipationless. If stars form in dwarf protogalactic fragments which then merge, this will result in a pressure-supported system, *i.e.*, a spheroid (bulge or halo, or an elliptical galaxy). Their metallicities will reflect the abundances in their parent systems.

Formation of Galaxy Disks and Dynamics of Stellar Populations

If protogalactic clouds merge dissipatively in a potential well of a dark halo, they will settle in a thin, rotating disk = the minimum energy configuration for a given angular momentum. If gas settles into a (dynamically cold) disk before stars form, then stars formed in that disk will inherit the motions of the gas (mainly an ordered rotation).

Chemical Self-Enrichment in Young Stellar Systems

In a massive system, supernova ejecta are retained, and reused for subsequent generations of stars, which achieve ever higher metallicities.

In a low-mass system, supernova shocks and star winds from massive young stars expell the enriched gas and may supress any subsequent star formation. The system retains its initial (low) metallicity.

13.3 Galaxy Interactions and Mergers

Merging / Interacting Systems

Galaxies in the process of a transformation, generally from disks to ellipticals

In late stages of a merger, the two galaxies are indistinguishable, and the product does not look like any standard galaxy type

Antennae Merger

Dust lanes in E galaxy NGC 1316

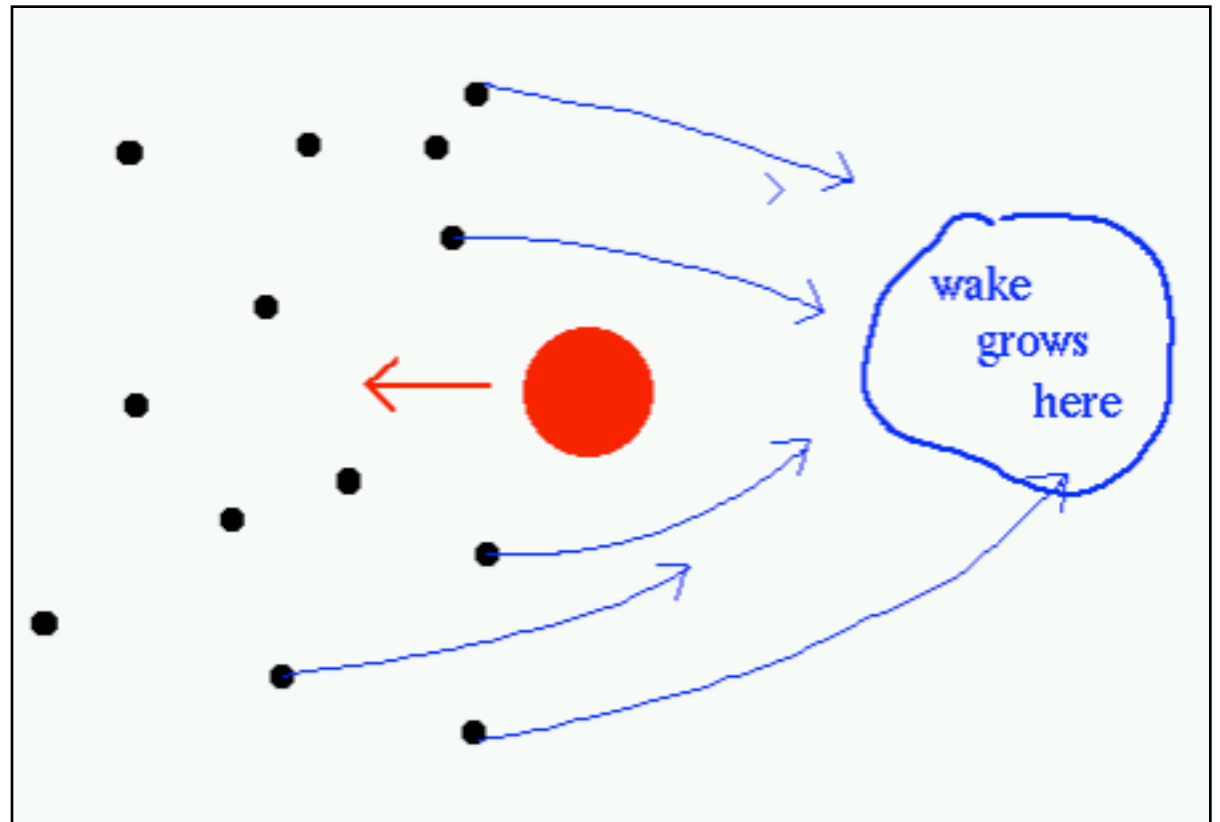

Dust is
surprisingly
common in E' s

Probably it
originates from
cannibalized
spiral galaxies

Dynamical Friction

- As a massive galaxy moves through a “sea” of stars (and the dark halo), it causes a wake behind it increasing the mass density behind it; the same effect applies to galaxy pass-bys
- This increase in density causes the galaxy to slow and lose its orbital kinetic energy
- The galaxy will eventually fall in and merge with its companion
- Local example: the Magellanic Clouds

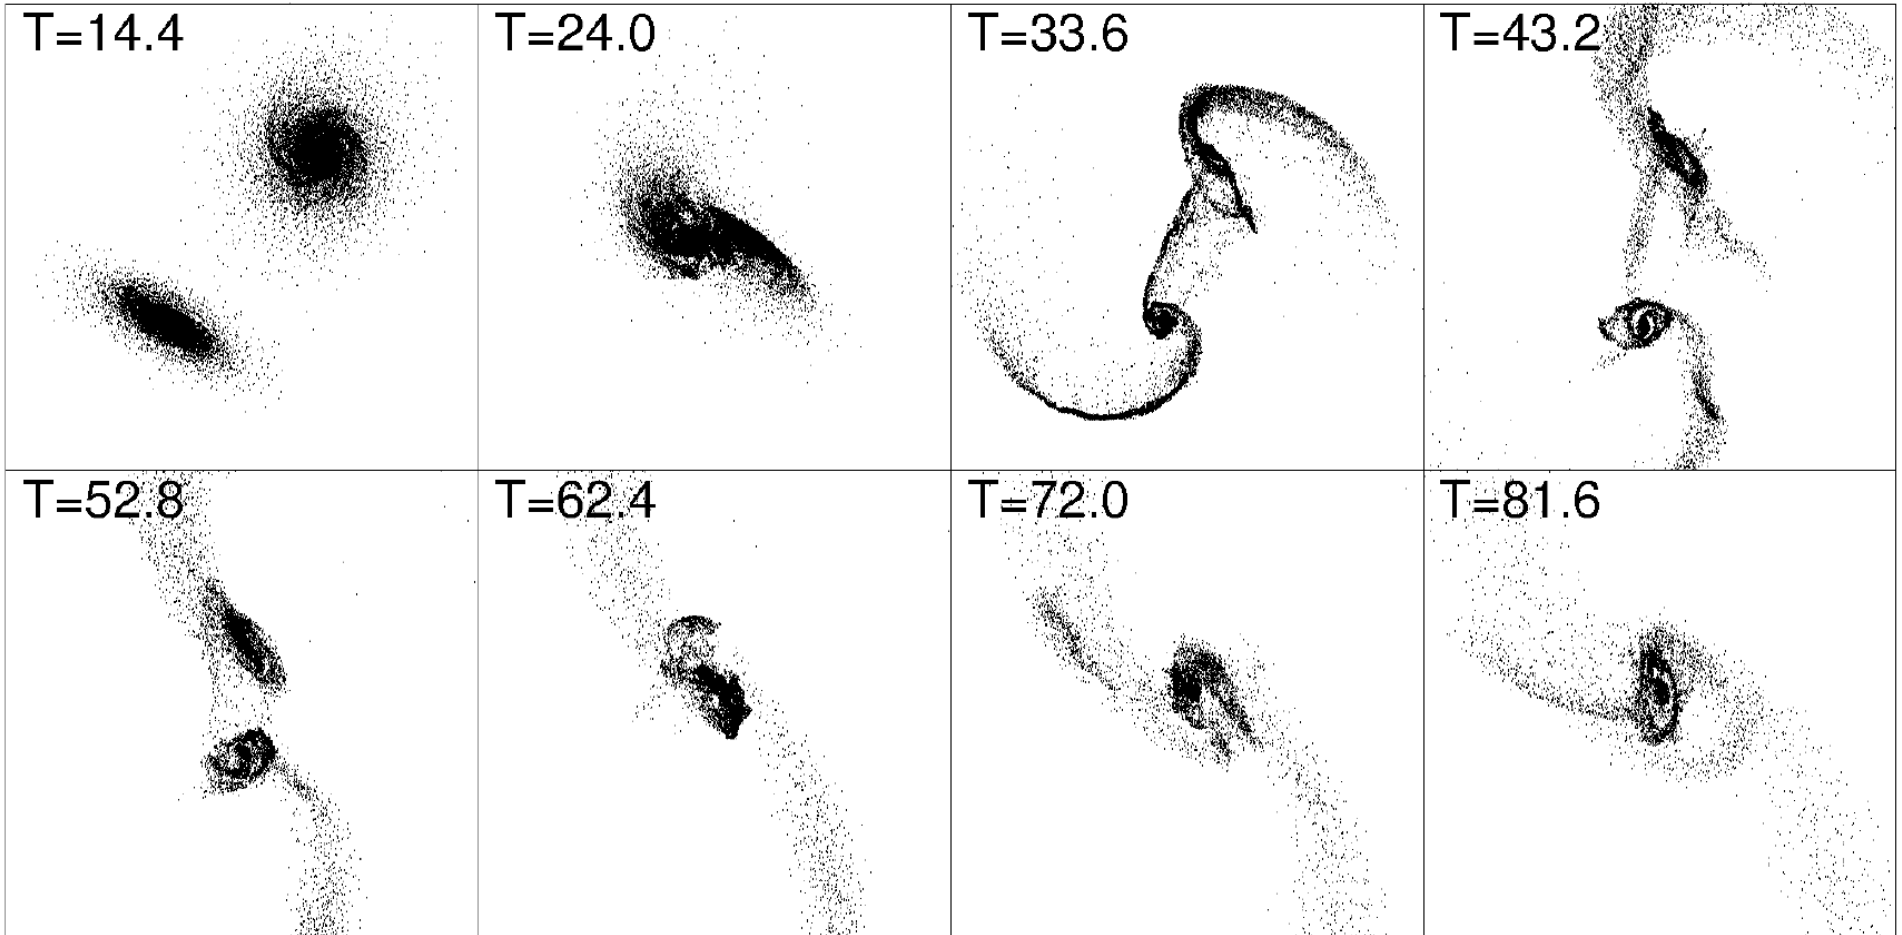

Galaxy Merger: Stars

Merge 2 nearly equal mass disk galaxies; in a few dynamical times, the remnant looks just like an elliptical galaxy

Galaxy Merger: Gas

In the same merger, gas quickly loses energy (since it is dissipative), and sinks towards the center of the remnant, where it can fuel a starburst, or an AGN if a massive black hole is present

13.4 Quantifying Galaxy Properties

Quantifying Properties of Galaxies

For galaxies of different types, we would like to quantify:

- The distribution of light - need photometric measurements
- The distribution of mass - need kinematical measurements
- Relative distributions and interplay of various components, e.g., stars, gas, dark matter - need multiwavelength measurements, as different components tend to emit most energy in different wavebands, e.g., stars → visible/near-IR, cold gas → radio, dust → far-IR, hot gas → x-rays, etc.
- Chemical composition, star formation rates - need spectroscopy

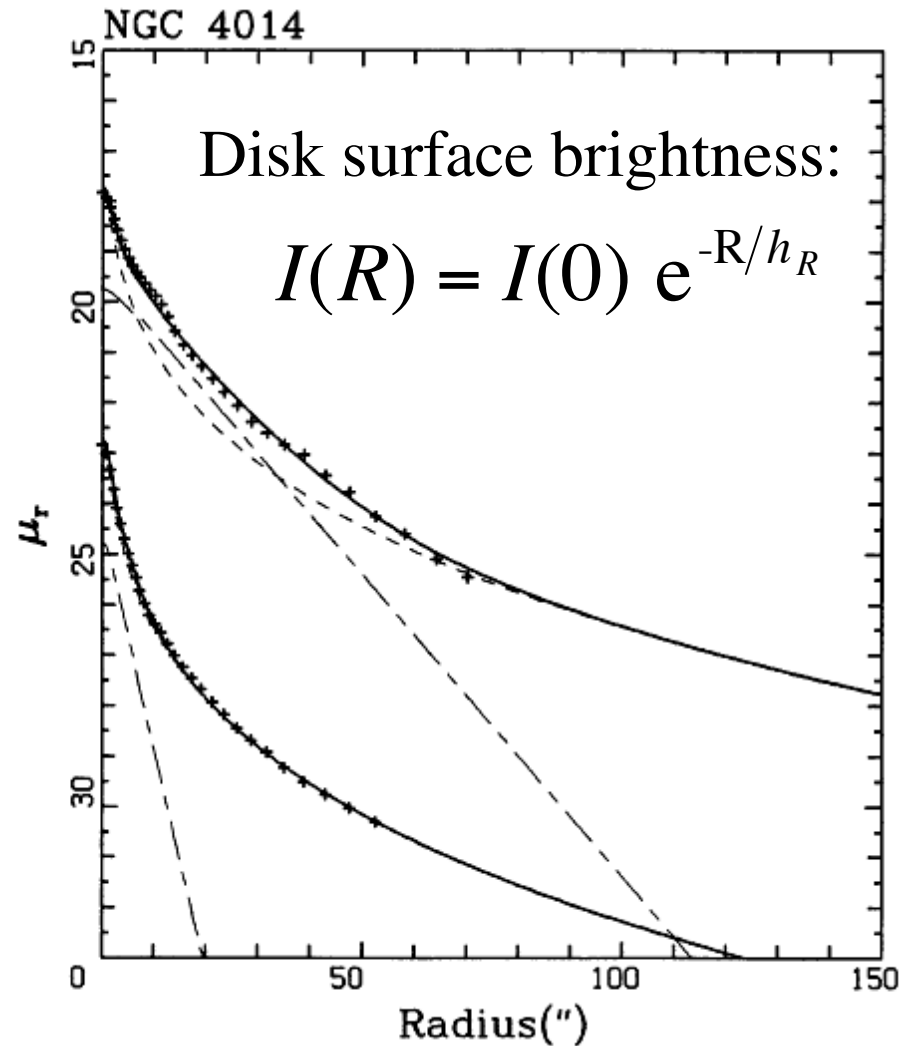

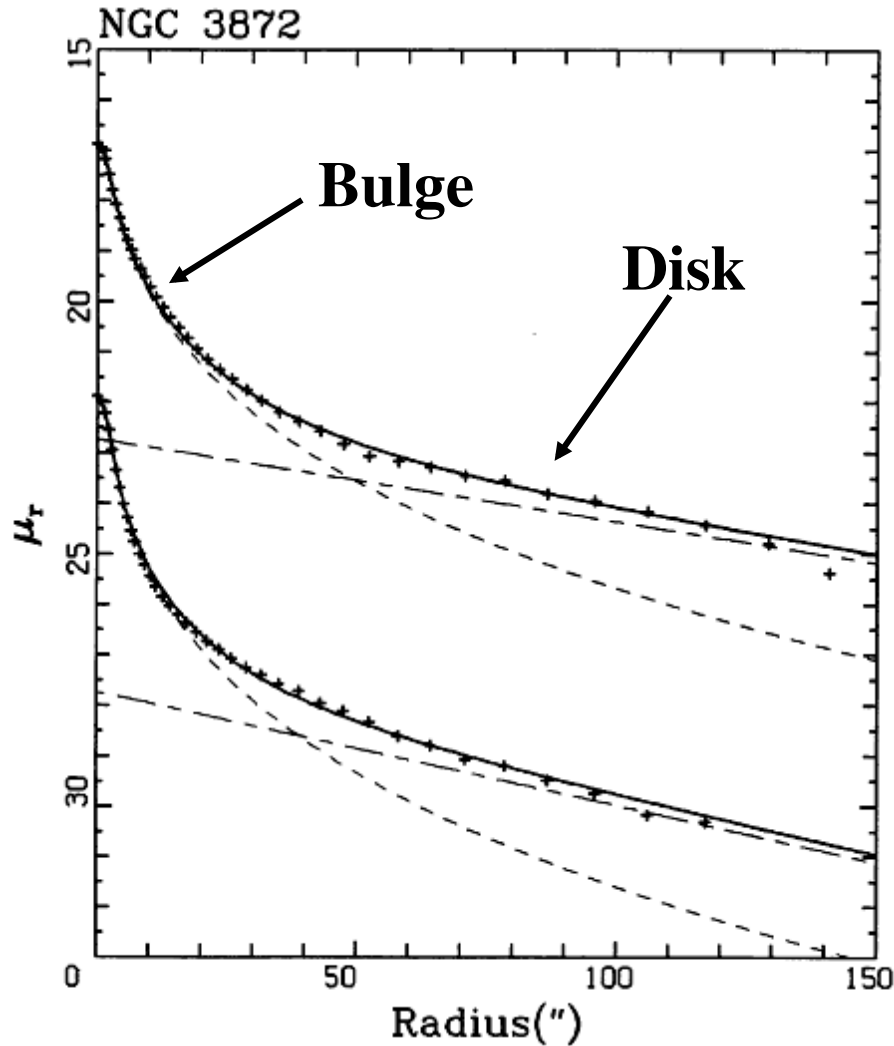

All these measurements can then be analyzed using:

- Dynamical models
- Stellar population synthesis models
- Galaxy evolution models

Note: we tend to measure different observables for different galaxy types!

Radial Surface Brightness Profiles of Spiral Galaxies

Note: semi-log profiles

(from S. Kent)

**NGC 1744:
H I contours
superposed
on a visible
light image**

Stellar disks
are *smaller*
than the gas
disks:
they probably
grow from
inside out

Molecular gas follows the spiral patterns

Elliptical Galaxies: Surface Photometry

Surface brightness profile is normally well represented by the $R^{1/4}$ or de Vaucouleurs law:

$$I(R) = I(0) e^{-kR^{1/4}}$$

where k is a constant.

This can be rewritten as:

$$I(R) = I_e e^{\left\{-7.67\left[\left(R/R_e\right)^{0.25} - 1\right]\right\}}$$

where R_e is the **effective radius**, containing half of the total luminosity, typically a few kpc

NGC 1700

Shapes of Ellipticals

- Ellipticals are defined by En , where $n=10\varepsilon$, and $\varepsilon=1-b/a$ is the ellipticity
- Note this is not intrinsic, it is observer dependent!

The observed distribution

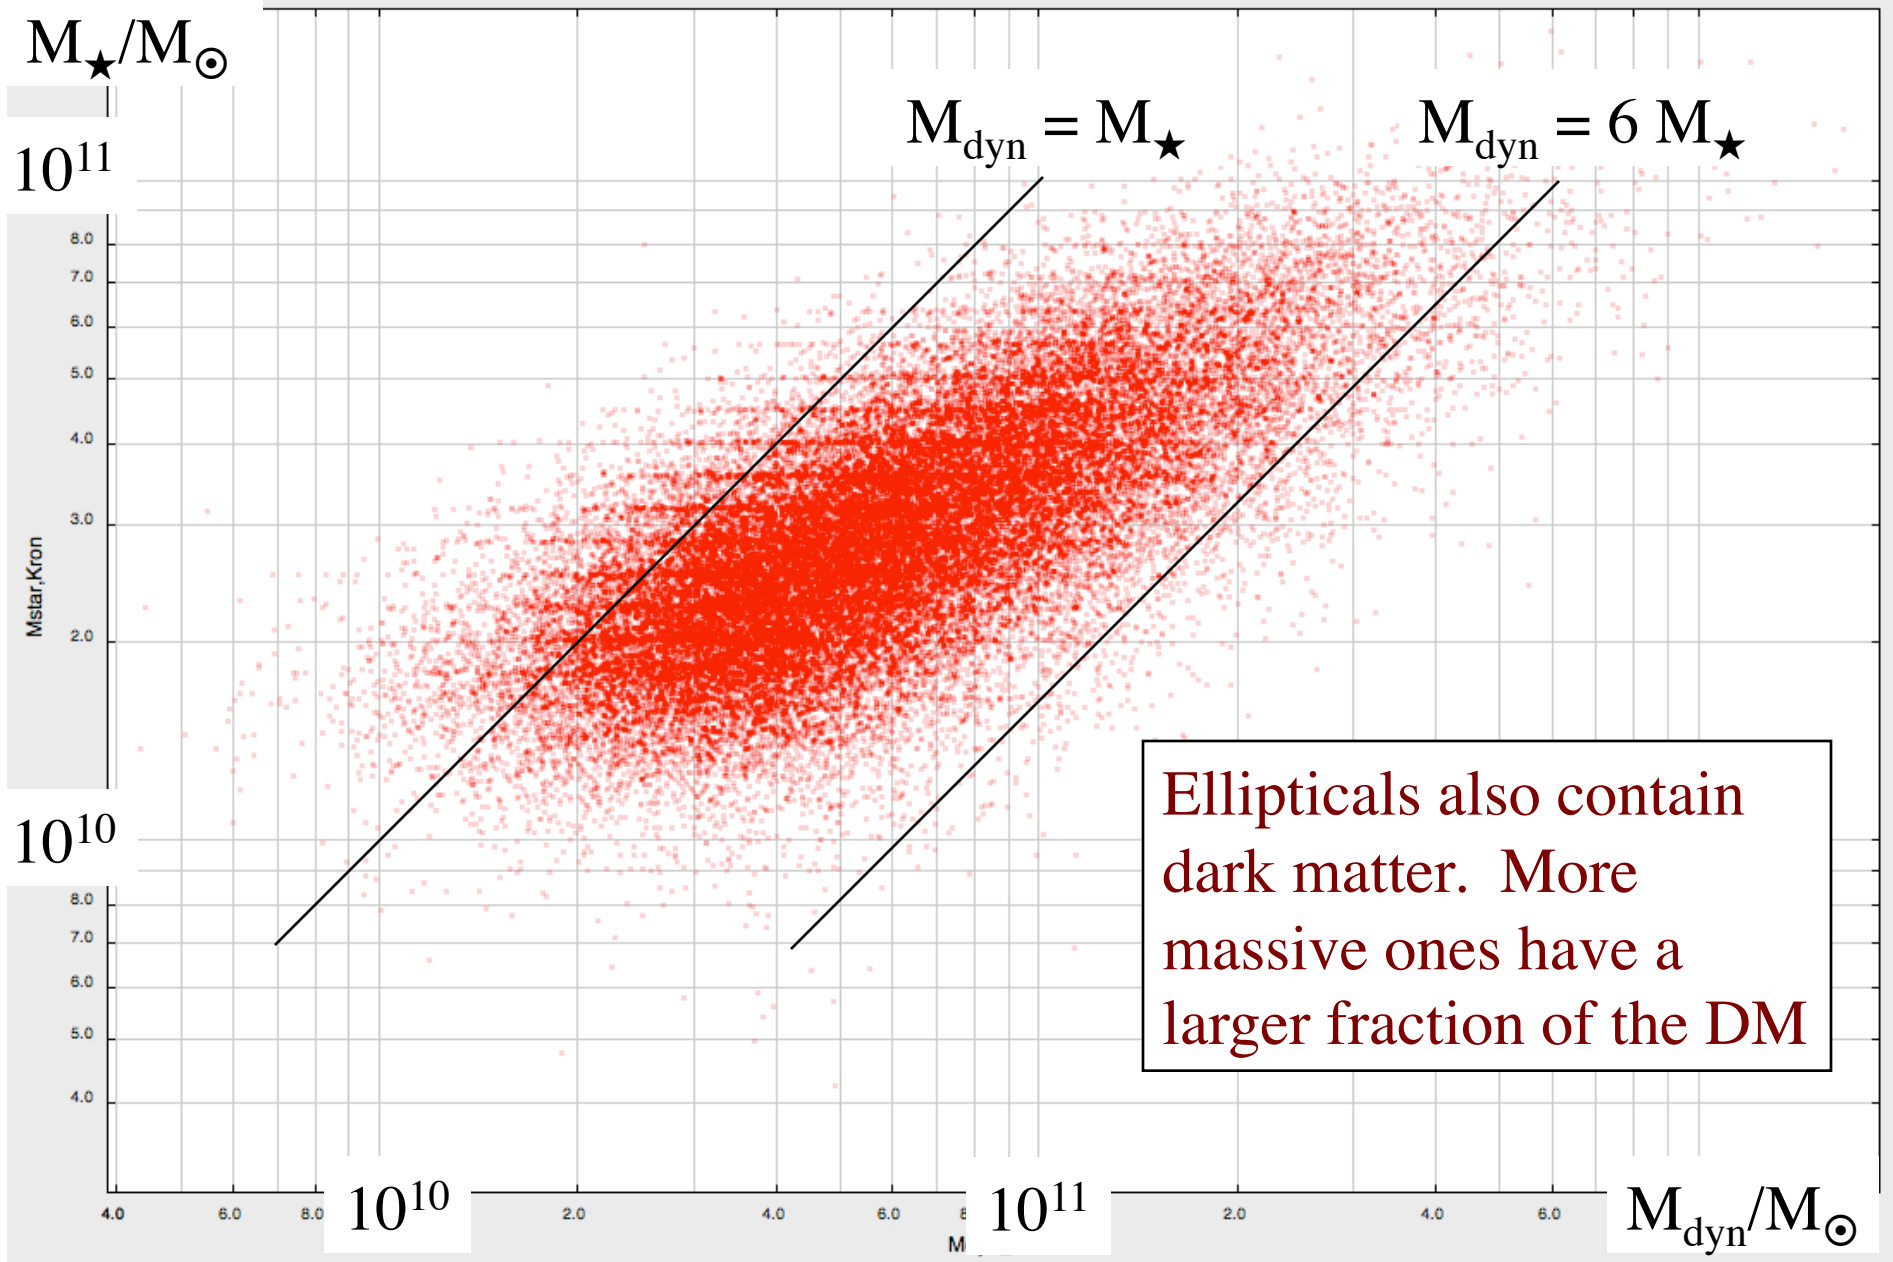

They Are Really Triaxial Ellipsoids

- In general, the 3-D shapes of ellipticals can be triaxial (A,B,C are intrinsic axis radii):
 - Oblate: $A = B > C$ (frisbee)
 - Prolate: $A > B = C$ (cigar)
 - Triaxial $A > B > C$ (football)
- It is due to **the anisotropic velocity dispersions** of stellar motions, which stretch the galaxies in proportion along their 3 principal axes
- Thus, elliptical galaxies are *not* flattened only by rotation
- Most of the kinetic energy is in random motions
- More massive ellipticals tend to be more anisotropic

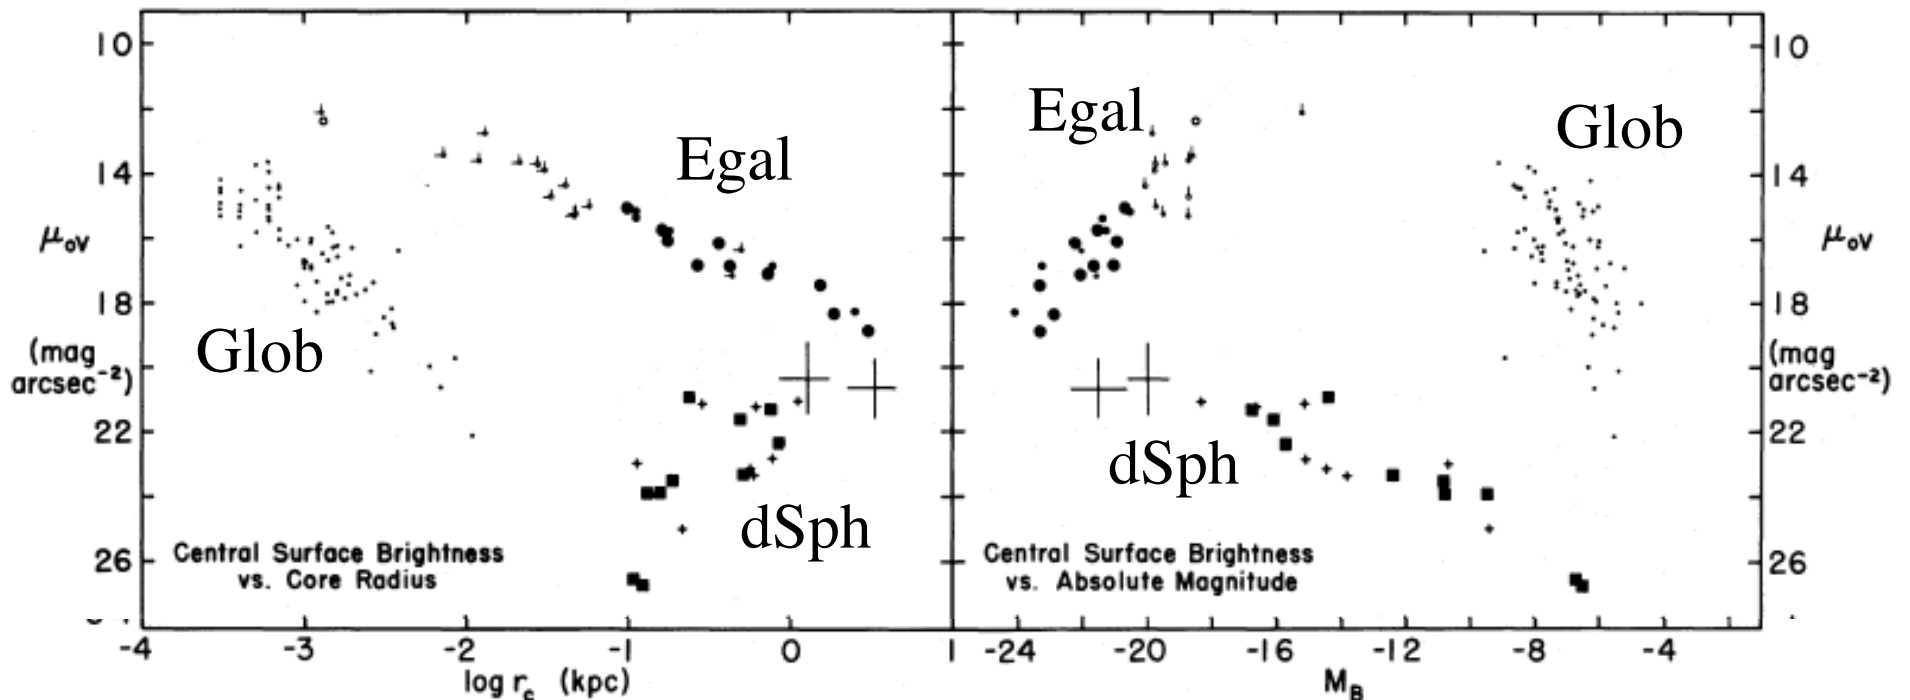

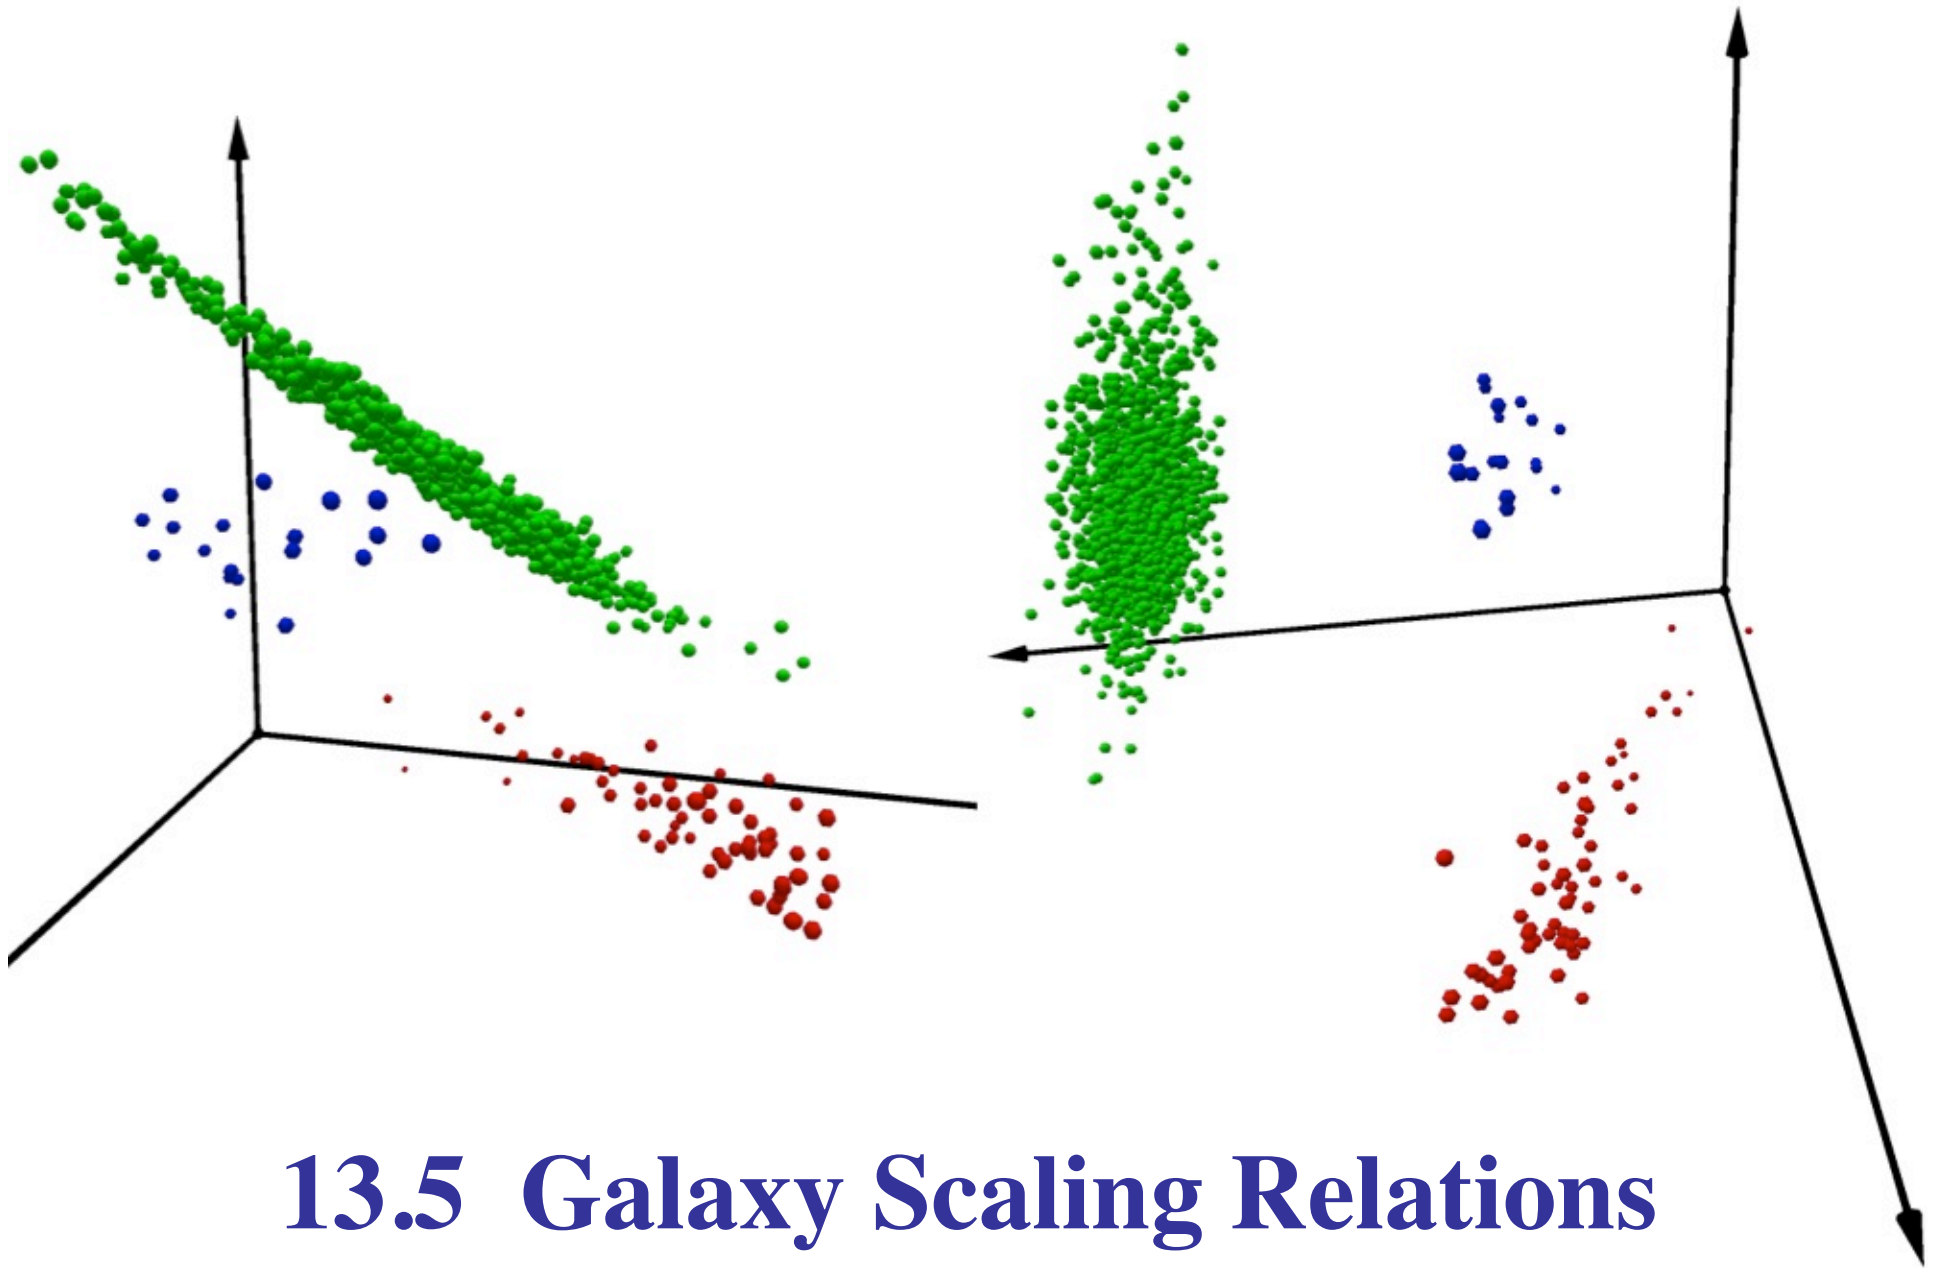

Stellar vs. Dynamical Mass

Dwarf Galaxies

- Dwarf ellipticals (dE) and dwarf spheroidals (dSph) are a completely different family of objects from normal ellipticals
- They follow completely different correlations from giant galaxies, suggestive of different formative mechanisms
- They are generally dark matter (DM) dominated, especially at the faint end of the sequence

13.5 Galaxy Scaling Relations

Galaxy Scaling Laws

- When correlated, global properties of galaxies tend to do so as power-laws; thus “scaling laws”
- They provide a *quantitative means of examining physical properties of galaxies* and their systematics
- They *reflect the internal physics* of galaxies, and are a product of the *formative and evolutionary histories*
 - They are different for different galaxy families
 - A “fossil evidence” of galaxy formation
- Correlations between distance-dependent and distance-independent quantities can be used to measure relative distances of galaxies

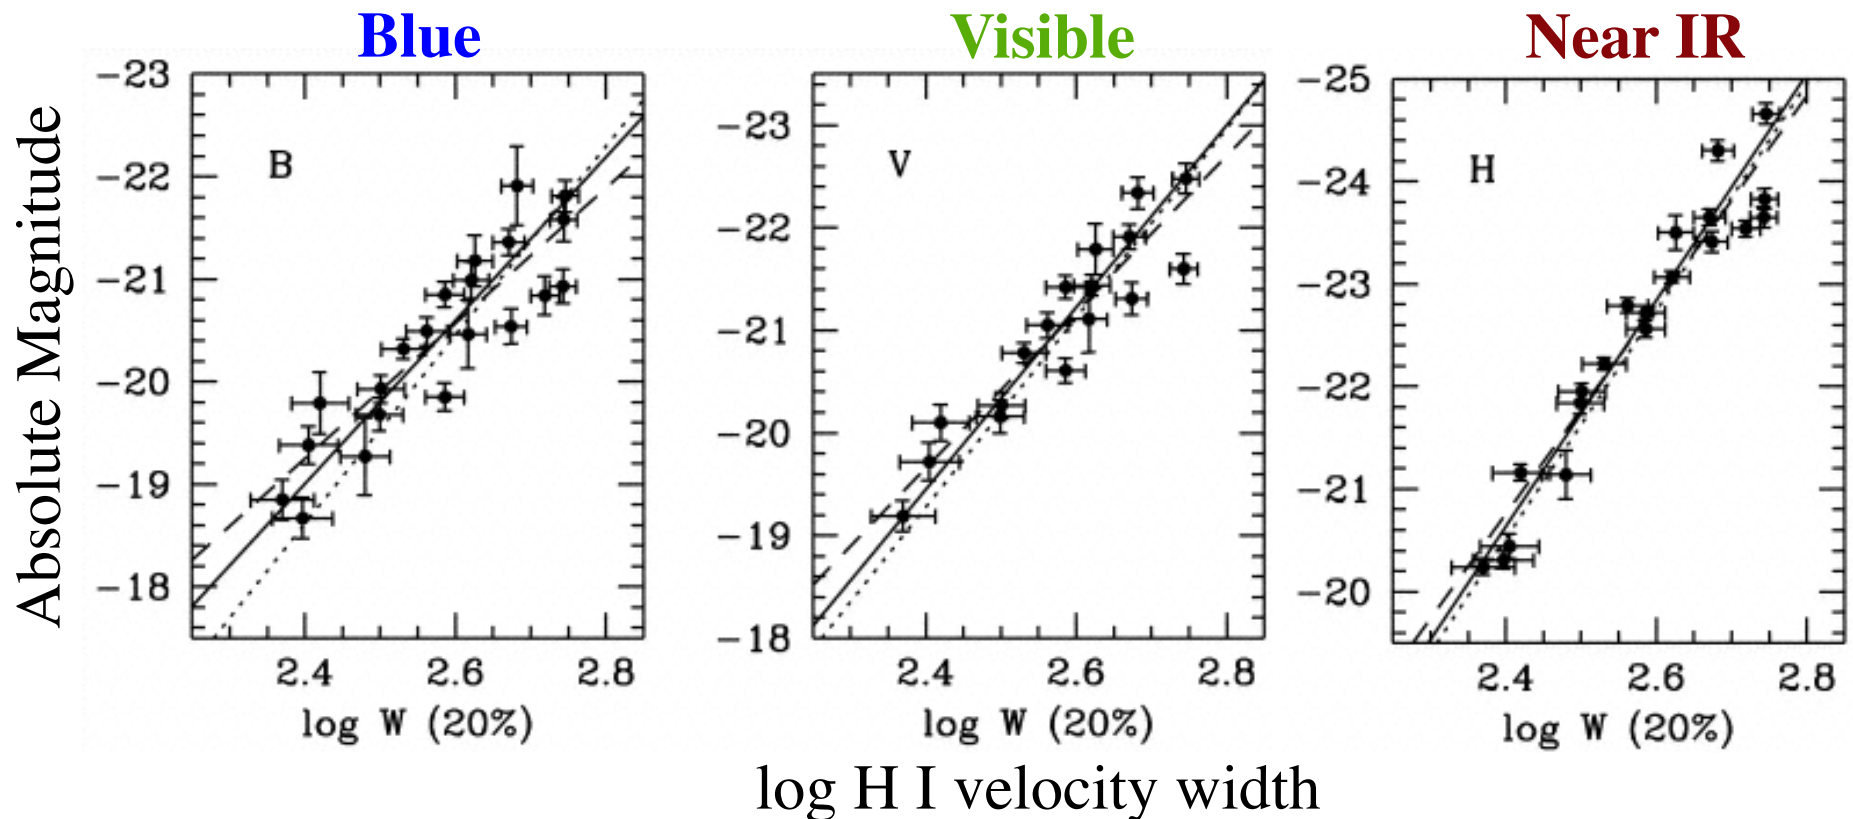

The Tully-Fisher Relation

- A correlation of luminosity vs. rotational speed (often measured as a H I 21 cm line width) relation for spirals:

$$L \sim V_{\text{rot}}^{\gamma}, \gamma \approx 4, \text{ varies with wavelength}$$

- Scatter is $\sim 10\%$ at best, better in the redder bands

Why is the TFR So Remarkable?

- Because it connects a property of the dark halo - the maximum circular speed - with the product of the net integrated star formation history, i.e., the luminosity of the disk
- Halo-regulated galaxy formation/evolution?
- The scatter is remarkably low - even though the conditions for this to happen are known not to be satisfied
- Thus, the TFR offers some important insights into the physics of disk galaxy formation
- And we use it to measure relative distances to spiral galaxies

Scaling Relations for Ellipticals

Many fundamental properties of ellipticals are connected through *bivariate scaling relations* (derive one from 2 others), called the **Fundamental Plane**, commonly expressed as a bivariate scaling relation $R \sim \sigma^{1.4} I^{-0.8}$, where R is the radius, I the mean surface brightness, σ the velocity dispersion

For any elliptical galaxy today, big or small,
Just Two Numbers

determine *to within a few percent or less*:

Mass, luminosity (in any OIR band),

Any consistently defined radius

Surface brightness or projected mass density

Derived 3-d luminosity, mass, or phase-space density

Central projected radial velocity dispersion

Optical and IR colors, line strengths, and metallicity

Mass of the central black hole

... and maybe other things as well

And they do so regardless of the:

Star formation and merging formative/evolutionary history

Large-scale environment (to within a few %)

Details of the internal structure and dynamics (including S0's)

Projection effects (the direction we are looking from)

Deriving the Scaling Relations

Start with the Virial Theorem: $\frac{GM}{\langle R \rangle} = k_E \frac{\langle V^2 \rangle}{2}$

Now relate the observable values of R , V (or σ), L , etc., to their “true” mean 3-dim. values by simple scalings:

$$R = k_R \langle R \rangle \quad V^2 = k_V \langle V^2 \rangle \quad L = k_L I R^2$$

One can then derive the “virial” versions of the FP and the TFR:

$$R = K_{SR} V^2 I^{-1} (M/L)^{-1}$$

$$L = K_{SL} V^4 I^{-1} (M/L)^{-2}$$

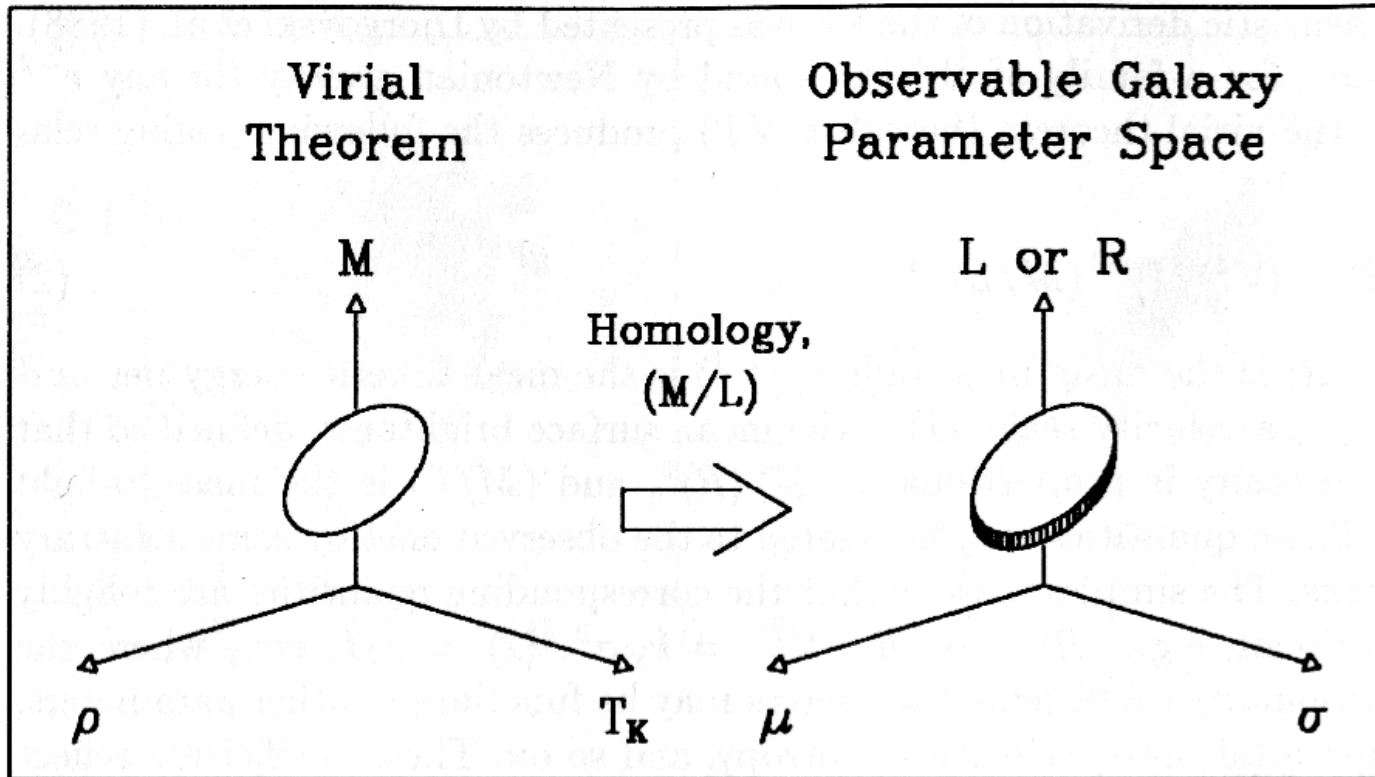

Where the “structure” coefficients are:

$$K_{SR} = \frac{k_E}{2Gk_Rk_Lk_V}$$

$$K_{SL} = \frac{k_E^2}{4G^2k_R^2k_Lk_V^2}$$

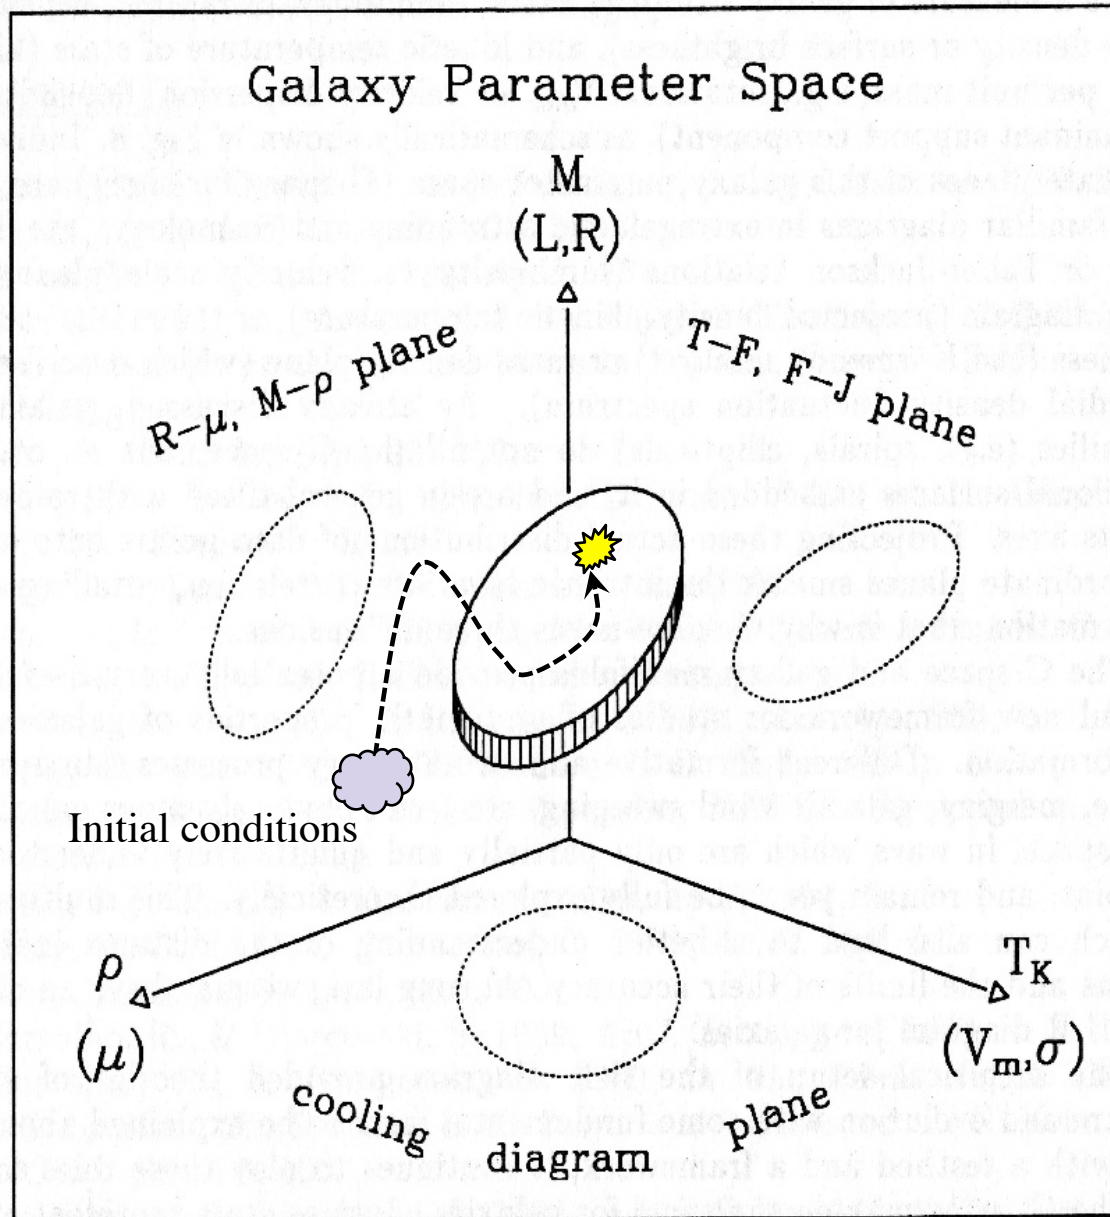

Deviations of the observed relations from these scalings must indicate that either some k 's and/or the (M/L) are changing

From Virial Theorem to FP

Virial Theorem connects mass, density, and kinetic temperature, and is thus an equation of a plane in that (theoretical) parameter space. Dynamical structure of ellipticals and their (M/L) ratios then map the VT into the tilted FP in the observable parameter space of measured quantities such as R, σ, I, L, \dots

The Galaxy Parameter Space

A more general picture

Galaxies of different families form 2-dim. sequences in a 3+ dimensional parameter space of physical properties, much like stars form 1-dim. sequences in a 2-dim. parameter space of $\{L, T\}$ - this is an equivalent of the H-R diagram, but for galaxies
